# What you really need to brew your first unfiltered beer at home

A well-chosen extract recipe, compatible ingredients and a few key measurements make the difference between learning from your first batch and making it harder than it needs to be.

Thursday, November 26, 2026

For a first homebrew, a coherent recipe and control of temperature and specific gravity matter more than collecting equipment. Educational illustration generated with AI.

Brewing unfiltered beer at home can be rewarding because you build a drink to your own taste and learn what changes when you adjust ingredients, temperature and timing. For a first batch, the sensible move is not to dive into advanced techniques, but to buy carefully, follow one compatible recipe and keep track of a few key measurements.

## Why it can be worth doing, and what unfiltered really means

The real appeal of a first homebrew is not the promise of a miraculous result. It is the chance to decide what each ingredient will do. Malt brings flavour, colour and body; hops shape bitterness and part of the aroma; and yeast does more than ferment, it also creates compounds that change the final profile. That gives you a way to learn what you like and either repeat it or adjust it next time.

Brewing an unfiltered beer simply means you do not apply a final filtration step to remove suspended particles and yeast before packaging. That alone does not make the beer better, more aromatic or higher quality: the effects of filtering or not filtering depend on the beer and on the process. An unfiltered beer can also be poured carefully so the sediment stays in the bottle, without shaking it or drinking the deposit at the bottom.

## Before you buy anything, choose an unhopped extract recipe

For a first batch, the clearest route is a recipe built around unhopped malt extract, hops and brewing yeast. Extract is concentrated wort: a liquid or powder made from malt that has already been processed, so you can skip mashing grain. That makes brewing simpler and reduces the amount of equipment, but it is still brewing. You do not need to buy grain as well for this first approach.

Before filling your shopping basket, find one complete recipe that matches that method. It should state the final batch volume, the type and amount of extract, the hop variety and when each addition goes in, the chosen yeast and the expected gravity readings. Specific gravity compares the weight of a given volume of wort or beer with the weight of the same volume of water. It helps you follow fermentation, but it does not directly measure sugar. The important thing is not to mix instructions from different recipes or confuse unhopped extract with a kit that already includes hops.

### Before you buy anything, your recipe should make these points clear

- Final batch volume.
- Type and amount of malt extract, clearly distinguishing syrup from powder.

- Hop variety and the timing of each addition.
- Chosen yeast and the temperature you can realistically maintain.
- Expected gravity readings to track fermentation.

## Ingredients: what to buy and what to check

Buy the malt extract your recipe calls for and stick to its format. It may come as syrup or powder, but you should not swap one for the other using the same weight because they are not equally concentrated. Hops also need to match the recipe: it is not enough for a variety to sound appealing, because both the variety itself and the point at which you add it during the boil matter. If you are brewing with this beginner route, extract, hops and yeast are one system, not separate purchases made by instinct.

Yeast deserves a practical decision: choose a strain that fits the recipe and, above all, a temperature you can genuinely maintain. The manufacturer’s instructions will tell you how to store it, how much to use and how to add it. It helps to separate fermentation temperature, which is the temperature the beer needs once the yeast has been pitched, from any separate instructions for rehydrating or preparing the yeast beforehand. A technical sheet applies to that specific strain, not to every yeast.

As for water, start with drinkable water that tastes pleasant. If you do not know its composition, there is no sense in imposing universal mineral adjustments or saying bottled water is always necessary. It is also worth checking the condition of everything you buy: poorly stored or old ingredients can harm the result, and no recipe can make up for tired raw materials.

If you plan to carbonate in the bottle, also buy the sugar required by the method you are following. That sugar is not there to sweeten the beer. It feeds a small fermentation inside the sealed bottle and creates the carbonation. The amount should not be guessed with teaspoons: it depends on the type of sugar, the real volume you will bottle and the level of carbonation you want.

## Basic equipment: what each piece is for

The essential gear for this first brew is functional and fairly short: a pot and heat source suited to your batch size, a washable food-safe fermenter with headspace for foam, a thermometer, a hydrometer with its test jar, a hygienic way to take samples, a scale, a long spoon, tubing or a siphon for transfers, a filling system and bottles with compatible closures. If you use crown caps, you will also need a capper. Together, these let you heat, measure, ferment and bottle without turning a beginner batch into an advanced setup.

The so-called gas-release bottle usually refers, in practice, to the fermenter’s airlock or bubbler. It is a small piece fitted to the lid or closure that lets carbon dioxide escape while limiting the entry of air. It is not the bottle the beer will be served from, and on its own it does not confirm that fermentation has finished: it may bubble for different reasons, or stop bubbling even though the process is not truly complete.

Some purchases are not necessary for this route: a grain mill, mash tun, beer filter, pressure fermenter or keg. A wort chiller can be useful, but it is an accessory, not a requirement. What matters is that the equipment you do use can be cleaned properly and matches your recipe volume.

### Starter equipment without turning it into an advanced setup

### Best to have from the first batch

A pot, heat source and washable fermenter with room for foam and an airlock.

A thermometer, hydrometer with test jar, scale and a hygienic way to take samples.

Tubing or a siphon, a filling system, pressure-safe bottles, compatible closures, cleaner and sanitiser.

**Can wait, or not needed for this route**

A grain mill, mash tun and beer filter.

A pressure fermenter or keg.

A wort chiller as a useful accessory, not a requirement.

## Cleaning and sanitising before you start

Before you make the wort, organise your space and treat hygiene as part of the process, not a minor detail. Cleaning and sanitising are not the same thing: cleaning removes visible dirt and organic residue; sanitising reduces the microorganisms that could spoil the beer. A piece of equipment can look clean without being sanitised, and a sanitiser will not work properly on dirt that has not been removed first.

Always follow the concentration, contact time and method of use for the product you choose. There is no universal mix that works for everyone. Pay closest attention to everything that will touch the wort once it has cooled, or the beer after fermentation: the fermenter, lid, airlock, spoon, siphon, test jar, filling system and bottles.

## Dissolving the extract and controlling the boil

Wort is the sugary liquid you have before fermentation starts. In this method, you make it by dissolving malt extract in water and bringing it to the boil with the hop additions set out in the recipe. From the start, two things are worth writing down: how long the boil lasts and the minute each hop addition goes in. That sequence affects the result and lets you repeat it or correct it later.

Do not treat one fixed boil time as a universal rule. Some beginner extract tutorials use 30 minutes, but that does not mean every brew must last the same length of time. The only valid schedule is the one in your complete recipe. For a beginner, what matters is not memorising a number but following one coherent formulation and recording what you do.

## Cool it down, adjust the volume and measure the original gravity

After the boil, the next step is to cool the wort with a method that suits your equipment and to protect it from unnecessary contamination. One option is to place the pot in a bath of cold water or ice, without letting that water get into the wort. Before adding the yeast, check the final volume called for by the recipe and use the thermometer to confirm that the liquid has reached the pitching temperature indicated for your yeast. Do not decide by touch or by room temperature: the reference point is the temperature of the wort and the instructions for the yeast you are actually using.

This is when you take the original gravity, meaning the reading of the wort before fermentation. To do it properly, draw a sample hygienically, transfer it to the test jar and read the hydrometer according to its scale and calibration temperature, applying a correction if needed. Do not pour that sample back into the fermenter. A hydrometer does not directly measure sugar or alcohol: it measures specific gravity, which is affected by dissolved substances and, after fermentation, by alcohol as well. By comparing the original and final readings, you can follow fermentation and estimate the strength later on. Once you have checked the volume, pitching temperature and original gravity, add the stated dose of yeast following its instructions and close the fermenter with the airlock fitted. The fermenter should not be sealed without a route for gas to escape.

## Fermentation: what to watch, and why not to trust the calendar alone

Fermentation is the yeast at work, turning sugars into alcohol and carbon dioxide. During this stage, what you mainly need to control is the temperature of the liquid and keep it within the recommended range for your strain. Opening the fermenter without a reason does not help; what does help is recording temperature, dates and the general look of the process.

The American Homebrewers Association’s extract-brewing tutorial places the fermentative phase on a one-to-two-week timescale, but that only gives you a sense of the process. It is not an automatic bottling date, and it is not a promise that every

batch will finish the same way. You also should not use airlock bubbling as decisive proof: whether it continues or stops does not replace a measurement.

The prudent check before moving on is another one: stable, comparable final gravity readings over more than 48 hours, consistent with what the recipe expects. If the gravity stops changing but still sits unusually high, it is worth reviewing the fermentation conditions before adding sugar and sealing bottles. Smell, appearance or the simple passage of days are not enough to declare it finished.

| Sign | How to read it |
| --- | --- |
| Final gravity stable for more than 48 hours and consistent with the recipe | This is the prudent check before adding sugar and sealing bottles. |
| The airlock stops bubbling | On its own, that is not enough to say fermentation is finished. |
| A few days, or one to two weeks, have passed | That only suggests the scale of the process; it does not set an automatic date. |
| Smell, appearance or intuition | They can support observation, but they do not replace a comparable measurement. |

## Calculate the sugar and bottle safely

When fermentation has genuinely finished, measure the real volume of beer you are about to bottle and calculate the sugar according to the type you are using and the carbonation you want. Conditioning is the period after bottling when that new fermentation creates gas and the beer finishes coming together. For dosing, the sensible move is to use a suitable brewing calculator and weigh the amount you need, not divide spoonfuls by eye. Before filling, add the sugar to the beer according to your chosen method and mix gently so it is distributed evenly, using hygienic equipment and avoiding splashing.

Use bottles designed for bottle-conditioned beer and pressure, in good condition and with compatible closures. Breakages can be linked to incomplete fermentation, contamination or too much sugar, so it pays to be methodical without becoming alarmist. During filling, work with sanitised equipment, avoid splashing and leave the coarsest sediment behind when transferring, but do not turn filtration into an obligation: an unfiltered beer does not need to be heavy with sediment to be well made.

## The final wait and how to serve an unfiltered beer

After bottling, the beer needs another waiting period to carbonate. The exact timing depends on the method, the yeast and the conditioning temperature the procedure calls for, which is why it makes sense to follow the timescale in weeks given by your reference, rather than a universal rule. As one documented example, some bottle-conditioning protocols ask for at least two weeks within a specific temperature range, but that does not automatically carry over to every strain.

When it is time to serve, chill the bottle, let it settle and pour carefully so you do not stir up the deposit at the bottom. That is a simple way to enjoy an unfiltered beer without dragging all the yeast into the glass. There is no need to shake the bottle or treat extreme cloudiness as the goal: the point is to pour better, not to show off sediment.

## Write the batch down so the next one improves

A simple record will help you more than memory. Note the recipe and batch volume, the type of extract, the hop variety, the yeast, the additions and when they went in, the wort temperature before pitching, the original gravity, the comparable final gravity readings, the dates of each check, the sugar added and any observations when serving. That record connects decisions to results and turns the next batch into a deliberate adjustment rather than a blind repeat.

### Minimum batch notes to learn from it

- Recipe, final volume and type of extract.

- Hop variety, additions and boil timings.
- Chosen yeast and wort temperature at pitching.
- Original gravity and comparable final readings.
- Fermentation dates, checks and bottling date.
- Sugar added and observations when serving.
